

Integrating biodiversity indices into a multi-species optimal control model

Christine Bertram*

July, 2010

Abstract: This paper explores the effects of integrating biodiversity indices that account for species richness and evenness into an economic optimal control model. Biodiversity is often adversely affected by human economic activities. This reduces social welfare but may be external to private economic decisions. Consequently, these external effects on biodiversity need to be considered explicitly in economic models, which is only partly reflected in the literature. Biodiversity is either treated only implicitly in models of multiple renewable resources, or it is considered in terms of (genetic) variability or species richness only, but not in terms of biodiversity indices that account for both species richness and evenness. However, both constitute important dimensions of biodiversity. This paper integrates non-use values derived from the existence of multiple renewable or living resources, expressed by such a biodiversity index, into a social welfare function. An optimal control model with an economic activity and two living resources is set up and conditions for optimal management are derived. Main findings are that a unique equilibrium that satisfies sufficient optimality conditions can be determined even though the biodiversity index is non-concave. Compared to a model set up with a monotonically increasing, concave value function, steady state stocks are distributed more evenly and biodiversity is higher when the biodiversity index is applied. However, the total number of individuals in steady state is higher when a monotonically increasing, concave value function is applied.

1 Introduction

Human activities and economic development are a continuous threat to biological diversity or biodiversity, which has given rise to calls for biodiversity conservation. Heal (2004) makes unequivocally clear that biodiversity creates and contributes to economic values. He distinguishes four categories to which biodiversity positively contributes: ecosystem productivity, insurance, genetic knowledge, and ecosystem services. Consequently, biodiversity does increase social welfare though it might be external to individual considerations of profit maximization. This has to be taken into account in economic models when determining efficient management strategies for the use of renewable and non-renewable resources. Not accounting for the adverse effects of economic activities on biodiversity implicitly means attaching a value of zero to it, which is not appropriate as highlighted by Heal (2004).

When attempting to introduce the notion of biodiversity into an economic model, biodiversity needs to be defined first. According to the United Nations Convention on Biological Diversity (CBD, 1992) it is "...the variability among living organisms from all sources including, inter alia, terrestrial, marine and other aquatic ecosystems and the ecological complexes of which they are part [which] includes diversity within species, between species and of ecosystems." This definition illustrates that biodiversity concepts can be applied to different organizational levels, i.e. the species-level or the community-level, and to different spatial scales (see Armswoth et al. (2004) for an overview of biodiversity concepts).

As this paper is concerned with the damage inflicted upon certain living species by economic activities like the extraction of non-renewable resources or the construction of roads in a confined area, it is reasonable to consider biodiversity on the species-level.¹ There are two general ways in which species-level biodiversity can be determined (Purvis and Hector, 2000). One way takes into account certain features of different species and calculates pairwise differences between the attributes of these species (Weitzmann, 1992). This concept can for example be applied to phylogenetic diversity, which would be larger the more the genetic features of the species differ. The second way is to set up a biodiversity index that takes into account the total

¹From now onwards the term biodiversity will be used to indicate species-level biodiversity throughout the paper although this will not always be explicitly mentioned.

number of species as well as the abundances of the different species. This paper follows the second approach, which is also widely used by ecologists.

Species-level biodiversity in this second sense has several dimensions. One dimension is species richness, which means the number of species within a certain area. This term was coined by McIntosh (1967) and it represents the oldest and most common measure of biodiversity. The second dimension of species-level biodiversity is species evenness, which means the variability in the distribution of species abundances within a certain area. While the role of species richness for biodiversity is intuitively clear, the role of evenness is subtler. From an ecological point of view, more abundant species usually have a larger influence on the functioning of ecosystems than rare species do. Consequently, considering an ecosystem with the same number of species, diversity increases the more evenly the species abundances are distributed. On the contrary, diversity decreases the more the ecosystem is dominated by few species (Duelli and Obrist, 2003; Armsworth et al., 2004).

Considering biodiversity only in terms of species richness implies that biodiversity loss only occurs when a species becomes extinct (Baumgaertner, 2006). This decline in species richness tends to receive special attention because species extinction is irreversible. Conserving species therefore means preserving a real option value in the sense that the function of a certain species and its contribution to ecosystem services, which might not be known today, will still be available in the future (Heal, 2004). However, Chapin et al. (2000) point out that "human activities influence the relative abundances of species more frequently than the presence or absence of species". They emphasize that changes in species evenness respond more quickly to human interference than changes in species richness do and that changes in species evenness have important impacts on ecosystems and their functioning long before a species is threatened by extinction (Chapin et al., 2000). So more generally, biodiversity loss can also occur when relative species abundances are changed, which should be accounted for and investigated also in economic models.

The two dimensions species richness and species evenness can be incorporated into a single measure by calculating so-called diversity indices.² There are a large number of different diversity indices (see Magurran (2004) for an overview) and they

²Following Good (1953), these indices are also called heterogeneity measures. However, throughout this paper they will be referred to as diversity or biodiversity indices.

are widely used in ecology to measure species-level biodiversity. However, the explicit integration of biodiversity into economic models still is scarce and according to a meta study by Eppink and van den Berg (2007), diversity indices that also account for species evenness have not been incorporated into economic models at all. If biodiversity is considered in economic models, it is either treated only implicitly in multi-species renewable resource models (e.g. Clark, 1976 or Swanson, 1994), or it is considered in terms of species richness (Li et al., 2001) or (genetic) variability (Brock and Xepapadeas, 2003). This paper integrates a biodiversity index that simultaneously accounts for species richness and species evenness into an optimal control model. The inclusion of such a biodiversity index allows to answer the question how economic activities like the optimal extraction of non-renewable resources or the construction of roads have to be adjusted if they have adverse effects on living resources and alter relative species abundances. Moreover, the index used provides a direct measure for biodiversity and no evaluation technique has to be used to infer the utility derived from biodiversity from empirical surveys.

2 Literature review

This paper introduces biodiversity indices into a multi-species optimal control model, where the living resources are damaged by some human-induced economic activity. The approach is similar to traditional harvesting models, where e.g. fish resources are harvested due to the possibility to generate profits, which have to be traded off against harvesting costs. Living resources, such as fish or other animals, usually do not grow linearly but e.g. according to a logistic growth function and face natural carrying capacities. The literature on renewable resources considers these biological constraints and investigates e.g. optimal harvesting programs or efficient management techniques.

Seminal papers on renewable resources include Gordon (1954), who highlights that the common property character of fish resources can lead to socially inefficient harvest. Clark and Munro (1975) use an optimal control approach to determine optimality conditions for harvest and resource stocks, and observe that non-linearities in the system can give rise to multiple equilibria. Clark (1979) determines optimal harvesting of a common property resource and compares it to the case of privately

owned fisheries. The standard one-species models of optimal fisheries have been extended to multiple-species models, where the species interact in different ways (see e.g. Clark, 1976). These interactions can be competing (Flaaten, 1991), mutualistic (Wacker, 1999) or predator-prey relationships (Hannesson, 1983).

The second strand of research important to this paper is that of biodiversity in economic models. Eppink and van den Bergh (2007) provide an extensive review of how biodiversity has been integrated into economic models, including those considering the optimal extraction of renewable resources. In these models, a value is typically attached to renewable resources due the possibility of harvesting them. Non-use values have also been captured in these models, e.g. as opportunity costs of land conservation where agricultural production yields positive returns but impacts negatively on the species abundances (Skonhøft, 1999 or Bulte and Horan, 2003). In addition, biodiversity can be a determinant for the resilience of an ecosystem against exogenous events. Perrings and Walker (1997) investigate the optimal management of ecosystems, where biodiversity and resilience are influenced by human interference. Biodiversity is thus often implicitly accounted for but only few papers include explicit indices to reflect direct or indirect values of biodiversity.

One way to consider biodiversity explicitly is to follow Weitzman (1992), who defines biodiversity in terms of pairwise differences between several features of different species. Brock and Xepapadeas (2003) build on this and establish an endogenous measure for biodiversity that accounts for the economic value derived from an ecosystem with genetic diversity. Moreover, Brock and Xepapadeas (2002) set up a model where two species compete for one resource and derive optimal management rules when the economic value derived from ecosystem functions is considered. Another way to consider biodiversity explicitly is to integrate biodiversity indices in terms of species richness into optimal control models. Li and Lofgren (1998) as well as Li et al. (2001) include information on species richness into their models to determine optimal paths for the number of species as well as for single resource stocks. In addition, Eichner and Tschirrhart (2007) use a biodiversity measure that is based on species abundances and constructed such that divergences from the natural level of biodiversity negatively impact on utility. They integrate this measure into a CGE modeling framework. Moreover, Eppink and Withagen (2009) integrate spatial patterns of biodiversity conservation into a multiregional general equilibrium model by

considering a species-area curve, where the number of species is a concave function of habitat size.

This literature review shows that there exist few papers that directly integrate biodiversity into economic considerations. This paper contributes to the literature by integrating a biodiversity index that accounts for both species richness and evenness into a multi-species optimal control model. The construction of the biodiversity index implies that the marginal value derived from an increase in the stock of one species may be positive or negative, depending on relative stock sizes. Qualitatively, this is similar to considering living renewable resources that may create both benefits and damages. One example for such a framework in a one-species model is presented by Rondeau (2001), who examines a model where the reintroduction of a harvested species may cause benefits and damages, while harvest itself creates benefits. Another example is presented by Horan and Bulte (2004), who consider living resources that may either create an economic benefit via tourism revenues or that induce a stock-dependent damage via agricultural damage or human mortality. Both frameworks allow for shadow prices that may either be positive or negative even in a one-species framework, which can give rise to non-convexities in the Hamiltonian as is also the case in Tahvonen and Salo (1996).

The model introduced in section 4 of this paper illustrates how a biodiversity index that may induce non-concavity of the current-value Hamiltonian influences the equilibrium values in an optimal control model with two living resources. It also shows how the characteristics of this equilibrium change compared to the case where the value derived from the living resources is monotonically increasing and concave in stock sizes and independent of relative stocks.

3 Biodiversity indices

Before presenting in more detail the group of biodiversity indices that are integrated into an optimal control model in section 4 of this paper, it has to be noted that employing these indices requires three basic assumptions. First, all species are assumed to be equal. Species with different conservation values or with different contributions to ecosystem functions are not discriminated but treated equally. Only the relative abundance of a species indicates its ecological importance. Second, all individuals

of the same species are assumed to be equal. The third assumption concerns the practical measurement of species abundances and assumes that they are recorded using appropriate and comparable units (Magurran, 2004).

The group of diversity indices used to represent biodiversity in this paper is based on an entropy measure that had originally been used in information theory (Renyi, 1961; Hill, 1973). This measure is constructed using the (relative) abundances of the species and thus (usually) accounts for species richness and species evenness. See Baumgaertner (2006) for a detailed discussion, which is briefly sketched in the following. The general biodiversity index is constructed as follows:³

$$V_\omega(x_1, \dots, x_n) = \left(\sum_{i=1}^n r_i^\omega \right)^{\frac{1}{1-\omega}} \quad \text{with } \omega \geq 0 \quad (1)$$

and

$$r_i = \frac{x_i}{\sum_{i=1}^n x_i} \quad \text{for } i = 1, \dots, n \quad (2)$$

The number of species under consideration is n . The relative abundance of each species $i = 1, \dots, n$ is given by r_i . This relative abundance is composed of the absolute abundance, x_i , of each species i relative to the sum of the absolute abundances of all species. As outlined in the introduction, the relative abundances of the species are important for their role within an ecosystem. All else being equal, the index value increases with increasing species richness but also with increasing evenness in the distribution of the relative abundances. The importance attached to species richness and evenness is determined by setting ω . For different values of ω , different biodiversity indices emerge (Baumgaertner, 2006).

There are two extreme cases. For $\omega = 0$, only species richness will be measured, but not evenness. Consequently, the resulting measure is just called Species Richness (R) (following McIntosh, 1967). The biodiversity index $V_0(\mathbf{x})$ always assumes the value n , reflecting the total number of species. A biodiversity loss only occurs if a species becomes extinct. For $\omega \rightarrow \infty$, only species evenness will be measured, but not richness. This measure is called Berger-Parker-Index (BP) (Berger and Parker, 1970). The biodiversity index $V_\infty(\mathbf{x})$ is given by $\{\max r_{it}\}^{-1}$. It thus only accounts

³In the following, the variables (x_1, \dots, x_n) will be collected in the vector (\mathbf{x}) .

for the species that is relatively most abundant. Biodiversity is given by the inverse of the relative abundance of this species.

All cases in between take into account both species richness and evenness but vary with respect to the degree of importance attached to either. There are two more cases with special names: The Shannon-Wiener-Index (SW) for $\omega = 1$ (Shannon, 1948; Wiener, 1948) and the Simpson-Index (S) for $\omega = 2$ (Simpson, 1949). The Shannon-Wiener-Index is based on the famous Shannon-Wiener entropy (H) used in statistics and information theory. It is computed as follows (for a formal proof see Hill, 1973):

$$V_1(\mathbf{x}) = \exp(H) = \exp\left(-\sum_{i=1}^n r_i \ln r_i\right) \quad (3)$$

The Simpson-Index is popular among ecologists because it has a meaningful ecological interpretation. It is computed as follows:

$$V_2(\mathbf{x}) = \left(\sum_{i=1}^n r_i^2\right)^{-1} \quad (4)$$

The sum of the squared relative abundances present in the Simpson-Index reflects the probability that any two individuals drawn randomly from an infinitely large ecosystem belong to different species. Biodiversity is represented by the inverse of this expression, so that $V_2(\mathbf{x})$ increases with increasing evenness in the distribution of relative species abundances (Baumgaertner, 2006).

The parameter ω that varies with the different indices can also be interpreted as the inverse of the elasticity of substitution between the relative abundances of the different species. The higher ω , the lower the elasticity of substitution between these relative abundances. So, for ω equal to one, this elasticity is one, for ω greater than one, substitution is relatively inelastic and for ω smaller than one, substitution is relatively elastic. Consequently, the higher ω the higher the value attached to evenness between the species. Neglecting evenness puts a relatively large weight on rare species (Baumgaertner, 2006). However, the qualitative characteristics of these indices are similar as long as $0 < \omega < \infty$.

For a given number of species, i.e. for a given value of n , the values of all indices are larger than 1 and smaller or equal to n , depending on the relative abundances

r_i . The relation between the different indices always is as follows:

$$n = V_0^R \geq V_1^{SW} \geq V_2^S \geq V_\infty^{BP} > 1 \quad (5)$$

The maximum value n is reached for $\omega > 0$ only if all species in an ecosystem have equal relative abundances, i.e. if $r_i = \frac{1}{n}$ for all i . For a given n and for $\omega > 0$, the value of $V_\omega(\mathbf{x})$ decreases with increasing unevenness in the distribution of relative abundances between the species. This is a very important and interesting feature of these biodiversity indices, which will be further discussed below and in subsection 4.2. The diversity indices are constructed such that for a given number of species n , they reach their maximum value only if all species have equal relative abundances. For example, for an ecosystem with two species, the biodiversity index takes on the maximum value 2 only if both species account for 50% of all individuals. But it does not matter how large their absolute abundance is. This also implies that increasing the absolute abundance of one species may lead to an increase in diversity or to a decrease of diversity, depending on whether this species had been underrepresented or overrepresented in the sample prior to the change.

In terms of economic thinking, this may seem counterintuitive. Usually, one assumes jointly concave utility functions where an increase in the availability of each good, for example, has a positive marginal utility. However, one can also think of backward-bending indifference curves where e.g. an increase in income has a negative marginal utility given that a high level of working hours has been reached. Using a diversity index in an economic model implies emphasizing the role of evenness in the distribution between two goods. More importantly, the utilization of diversity indices is widely used in ecology because the distribution of abundances matters for the functioning of ecosystems. Consequently, it seems worthwhile to explore the role of diversity indices also in economic models where external effects on relative species abundances and biodiversity occur.

4 Biodiversity in an optimal control model

4.1 General modeling framework

In this subsection, the general biodiversity index as described in section 3 is incorporated into an optimal control model. The model is set up as follows:

$$\max W = \int_0^{\infty} e^{-\rho t} [U(y_{1t}, \dots, y_{nt}) + V(x_{1t}, \dots, x_{nt})] dt \quad (6)$$

s.t.

$$\dot{x}_{it} = G_i(x_{1t}, \dots, x_{nt}) - \phi_i y_{it} \quad \text{and} \quad x_{i0} = X_i \quad \text{for} \quad i = 1, \dots, n \quad (7)$$

and

$$G_i(x_{1t}, \dots, x_{nt}) = \psi_i x_{it} \left(1 - \frac{\sum_{j=1}^n x_{jt}}{\kappa}\right) \quad \text{with} \quad 0 < \sum_{j=1}^n x_{jt} \leq \kappa \quad \forall i, t \quad (8)$$

In this model, the instantaneous utility function $U(y_{1t}, \dots, y_{nt}) = U(\mathbf{y}_t)$ expresses the net benefit generated by some economic activity, e.g the extraction of non-renewable resources, construction activities or agricultural activities, at time t . The vector $\mathbf{y}_t = (y_{1t}, \dots, y_{nt})$ describes the level or intensity of this economic activity but it is not further specified. Especially, there is no explicit modeling of the costs related to this activity. This simple modeling approach has been chosen to be able to clearly identify the effects of the second factor contributing to social welfare, the biodiversity index, on the model solutions. The instantaneous utility function is separable in the components of \mathbf{y}_t and satisfies the following properties: $\frac{\partial U(\mathbf{y}_t)}{\partial y_{it}} = U_{y_{it}} > 0 \quad \forall i, t$; $U_{y_{it}y_{it}} < 0 \quad \forall i, t$ and $U_{y_{it}y_{jt}} = 0 \quad \forall i \neq j, t$. The vector $\mathbf{x}_t = (x_{1t}, \dots, x_{nt})$ contains the stocks of the n renewable or living resources at time t . The value derived from their existence is expressed by the biodiversity index $V(x_{1t}, \dots, x_{nt}) = V(\mathbf{x}_t)$. The properties of this biodiversity index are crucial for the solutions of the model and discussed below in more detail.

The case that n may change is not considered here, which implies that no species becomes extinct and that the number of species cannot be increased. This is reasonable because the economic activity takes place in an environment with a given ecosystem and thus with a given number of species. It is assumed that a social planner intends to maximize social welfare by integrating the discounted utility and

value functions over time. In this partial equilibrium model, $U(\mathbf{y}_t)$ and $V(\mathbf{x}_t)$ are both given in money metrics and therefore enter the social welfare function separably.

Conditions (7) and (8) together define the equations of motion for the stocks of the living resources x_i . Note that the growth of each living resource does not only depend on its own stock size but also on the stock sizes of all other living resources. In this specification, all living resources compete for the same external resource, which may be food supply.⁴ In the absence of the other living resources, the biomass stock of one living resource x_i would grow according to a logistic growth law. The growth function $G_i(\mathbf{x})$ defined in (7) would then take on the form of a concave quadratic function dependent only on x_i with $G_i(0) = 0$ and $G_i(\kappa) = 0 \quad \forall i$. The maximum growth rate would be reached when the stock is equal to $\frac{\kappa}{2}$. The parameter ψ_i represents the intrinsic growth rate of the stock x_i , and κ represents the carrying capacity of the stock.

In addition, it is assumed that the economic activity expressed by \mathbf{y} reduces the stock of the living resource according to the damage coefficient ϕ_i . Note that there is one separate control variable y_i for each living resource stock x_i . This implies that the damage caused by the economic activity can be controlled separately for each living resource, which is similar to fishery models with selective harvesting (see e.g. Clark, 1976). Assuming that the damage would be non-selective would impose rigidities on the model that would induce the possibility of negative shadow prices and thus the existence of multiple equilibrium candidates. The more flexible approach has been chosen here to allow a better analysis of the behavior of the biodiversity index in the model. Moreover, it seems by no means impossible that economic activities like the construction of roads can be executed such that the damage inflicted upon different living species can be controlled separately.

Note moreover, that this is only one way in which the negative impact of economic activities on living resources could be modeled. Another possibility would be that these activities damage the habitat of the living resources, such that the carrying capacity κ would be reduced. However, here the impact takes place in the form of a flow externality, reducing the biomass stock of the renewable resource whenever the economic activity is carried out.

⁴The specification is a modified version of the Gause model (Gause, 1935) as described by Clark (1976). Especially, it is assumed here that $\kappa_i = \kappa \quad \forall i$ for simplicity.

The current-value Hamiltonian now reads as follows:⁵

$$H^c = U(\mathbf{y}) + V(\mathbf{x}) + \sum_{i=1}^n \lambda_i (G_i(\mathbf{x}) - \phi_i y_i) \quad (9)$$

The necessary first order conditions are given by expressions (10) to (11).

$$\frac{\partial H^c}{\partial y_i} = 0 \quad \Rightarrow \quad U_{y_i} = \phi_i \lambda_i \quad \forall i \quad (10)$$

$$-\frac{\partial H^c}{\partial x_i} = \dot{\lambda}_i - \rho \lambda_i \quad \Rightarrow \quad \rho = G_{ix_i} + \sum_{j \neq i} \frac{\lambda_j}{\lambda_i} G_{jx_i} + \frac{\dot{\lambda}_i}{\lambda_i} + \frac{V_{x_i}}{\lambda_i} \quad \forall i \quad (11)$$

The conditions given by (10) represent the static optimality conditions for the optimal level of the economic activity at each point in time. The marginal utility of this activity has to be equal to its marginal costs. As the costs are not explicitly considered here, the right-hand-sides of the equations only include the damage on the living resources caused by the economic activity, evaluated with the corresponding shadow price, λ_i , of the living resource x_i . With each unit of the economic activity carried out, a certain share of the stocks of the living resources is destroyed. This implies opportunity costs because this share of the living resources will not be present in the future to contribute to reproduction, thus diminishing the own rate of interest of the living resources. As by assumption $U_{y_i} > 0$ and $\phi_i > 0$, the optimality conditions in (10) imply that $\lambda_i > 0 \forall i$.

The conditions given by (11) describe the optimal allocation of each stock of the living resources over time. Expressed in capital theoretic terms, the social discount rate ρ has to be equal to the own rate of interest of each living resource stock. This own interest rate consists of the growth rate of the resource stock x_i (G_{ix_i}), the impact of the resource stock on the growth rate of all other living resource stocks evaluated with the corresponding shadow prices ($\sum_{j \neq i} \frac{\lambda_j}{\lambda_i} G_{jx_i}$), the increase in its own shadow price ($\frac{\dot{\lambda}_i}{\lambda_i}$) and the increase in the existence value derived from this stock, i.e. the increase in the biodiversity index divided by the shadow price ($\frac{V_{x_i}}{\lambda_i}$).

⁵Time subscripts are dropped for convenience where this does not lead to confusion. The variables (x_1, \dots, x_n) and (y_1, \dots, y_n) are collected in the vectors (\mathbf{x}) and (\mathbf{y}) respectively.

4.2 Properties of the biodiversity indices

Subsection 4.1 presented a general version of the model for n species and incorporated a general version of the biodiversity index, $V(\mathbf{x})$, in the optimization framework. In this subsection, the properties of the biodiversity indices, especially their reaction to changes in the stock size of a living resource, and the resulting impacts on the optimal control model are traced analytically in more detail for different values of ω .

Species Richness. Suppose that $\omega = 0$. This implies that biodiversity will only be measured by means of the total number of species n and $V_0(\mathbf{x}) = n$. So, as long as n stays constant, i.e. as long as no species is driven to extinction by the damage caused by the economic activity, $\frac{\partial V_0(\mathbf{x})}{\partial x_i} = 0$ for $i = 1, \dots, n$, and the conditions in (11) reduce to:

$$\rho = G_{ix_i} + \sum_{j \neq i} \frac{\lambda_j}{\lambda_i} G_{jx_i} + \frac{\dot{\lambda}_i}{\lambda_i} \quad \forall \quad i \quad (12)$$

At first sight, this suggests, that the stocks of the living resources are not important for the optimal path of the economic activity over time. However, the opportunity costs of destroying shares of the stocks of the living resources are still present in equations (10), implying that the damage inflicted upon the living resources does still matter for the optimal path of the economic activity \mathbf{y} . This is because decreasing the stock of the living resources still induces reduced opportunities for future stock growth.

Berger-Parker-Index. Suppose that $\omega = \infty$ and denote the relatively most abundant living resource stock by x_m , so that $V_\infty(\mathbf{x}) = r_m^{-1} = \frac{\sum_{i=1}^n x_i}{x_m}$. From this it follows that:

$$\frac{\partial V_\infty(\mathbf{x})}{\partial x_m} = \frac{x_m - \sum_{i=1}^n x_i}{x_m^2} = \frac{-\sum_{i \neq m} x_i}{x_m^2} < 0 \quad (13)$$

Note that this partial derivative is negative as long as there exist more species than just the species m with a positive number of individuals each. This implies that an increase in the stock of the most abundant species necessarily leads to a reduction of biodiversity and thus to a decrease in utility derived from this stock increase. The reason for this is obvious: Increasing the stock size of the species that is already dominant in the sample increases the unevenness and thus decreases

diversity. On the other hand, an increase in the abundance of any non-dominant species x_i with $i \neq m$ will necessarily increase biodiversity:

$$\frac{\partial V_\infty(\mathbf{x})}{\partial x_i} = \frac{1}{x_m} > 0 \quad \forall \quad i \neq m \quad (14)$$

Simpson-Index. As it is the aim of the paper to consider both species richness and evenness and not only one of them, it will be assumed from now on that $V(\mathbf{x})$ is given by the Simpson-Index with $\omega = 2$. This is sensible because the Simpson-Index has a meaningful ecological interpretation. In addition, the Simpson-Index is "one of the most meaningful and robust diversity measures available" (Magurran, 2004). It should be noted here that the Simpson-Index puts a relatively large emphasis on evenness compared to richness. However, this is appropriate here because the model considers an environment with a fixed number of species. Moreover, the Simpson-Index is representative for all cases in which $0 < \omega < \infty$. The derivatives presented below have also been derived for the general case, and qualitative features, especially the results derived from equation (17), also hold in general. Consequently, the assumption $\omega = 2$ does not entail any loss of generality. Note also that for the sake of concreteness, the number of species will from now on be reduced to $n = 2$. It follows that:

$$V_2(x_1, x_2) = V_2(\mathbf{x}) = (r_1^2 + r_2^2)^{-1} \quad (15)$$

with

$$r_i = \frac{x_i}{x_1 + x_2} \quad \text{for } i = 1, 2 \quad (16)$$

Partially differentiating $V_2(\mathbf{x})$ with respect to x_1 yields the following derivative. The partial derivative V_{x_2} can be constructed analogously.

$$V_{x_1} = -2 * V_2(\mathbf{x})^2 * (x_1 + x_2)^{-3} * [x_2(x_1 - x_2)] \quad \left\{ \begin{array}{l} < 0, \quad x_1 > x_2; \\ = 0, \quad x_1 = x_2; \\ > 0, \quad x_1 < x_2. \end{array} \right. \quad (17)$$

It is obvious that the effect of an increase in the abundance of one species does not necessarily lead to an increase in the value of the biodiversity index. If x_1 is underrepresented in the sample, i.e. $x_1 < x_2$, an increase in its stock size will lead to higher biodiversity. But if it is overrepresented in the sample, i.e. $x_1 > x_2$, an

increase in its stock size will lead to lower biodiversity. This is the main difference to other renewable resource models where the marginal utility of the stock usually is positive for all stock sizes.⁶

If all species are equally abundant, i.e. $x_i = x' \forall i$, the derivative of $V_2(\mathbf{x})$ with respect to each x_i is zero. That is, diversity has reached its maximum value, n , and will not further increase with an increase in the relative abundance of any species because all species are equally abundant. (Sufficient conditions for a maximum are checked below.) However, biodiversity will decline whenever the size of any stock diverges from x' because evenness is no longer fully satisfied. This holds for all ω .

Constructing the general Hessian matrix composed of the second partial derivatives of $V_2(\mathbf{x})$, one receives the following:

$$He(V_2(\mathbf{x})) = \begin{pmatrix} V_{x_1x_1} & V_{x_1x_2} \\ V_{x_2x_1} & V_{x_2x_2} \end{pmatrix} = \begin{pmatrix} \frac{4x_1x_2(x_1^2-3x_2^2)}{(x_1^2+x_2^2)^3} & \frac{-2(x_1^4-6x_1^2x_2^2+x_2^4)}{(x_1^2+x_2^2)^3} \\ \frac{-2(x_1^4-6x_1^2x_2^2+x_2^4)}{(x_1^2+x_2^2)^3} & \frac{4x_1x_2(-3x_1^2+x_2^2)}{(x_1^2+x_2^2)^3} \end{pmatrix} \quad (18)$$

The eigenvalues and the determinant of this Hessian are as follows:

$$EV_1(He) = \frac{2(x_1 - x_2)^2}{(x_1^2 + x_2^2)^2} \geq 0 \quad (19)$$

$$EV_2(He) = \frac{-2(x_1 + x_2)^2}{(x_1^2 + x_2^2)^2} \leq 0 \quad (20)$$

$$Det(He) = \frac{-4(x_1^2 - x_2^2)^2}{(x_1^2 + x_2^2)^4} \leq 0 \quad (21)$$

This allows to draw important conclusions for the curvature of the biodiversity index $V_2(\mathbf{x})$. Two cases can be distinguished:

Case 1: $x_1 = x_2$. In this case, the first partial derivatives of the biodiversity index, V_{x_1} and V_{x_2} , are zero and $V_2(\mathbf{x})$ assumes the critical value $n = 2$. Moreover, it now holds that the first eigenvalue $EV_1(He)$ is zero while the second one is negative. In addition, the determinant of He is zero. From this it follows that He is negatively semi-definite and thus $V_2(\mathbf{x})$ is locally concave for $x_1 = x_2$. Consequently, the critical

⁶Two exceptions are Rondeau (2001) and Horan and Bulte (2004), who account for the possibility of negative marginal utility in a one-species framework.

value $n = 2$ is proven to be a maximum.

Case 2: $x_1 \neq x_2$. In this case, the eigenvalues of He necessarily are of different signs and the determinant of He is negative, so that He is indefinite and no conclusions can be drawn for the curvature properties of $V_2(\mathbf{x})$.

As the Simpson-Index is locally concave in x_i only for $x_1 = x_2$ and not for all combinations of x_1 and x_2 , also the Hamiltonian will not necessarily be jointly concave in the control and state variables on the whole domain. This will make a special analysis of the equilibrium candidates necessary. A concave Hamiltonian (together with the condition of non-negative shadow prices) would ensure that there exists a unique equilibrium which would necessarily be a maximum and thus part of an optimal solution. However, the non-concavity of the Hamiltonian requires a more subtle analysis here.

4.3 Analytical features of the model

Rearranging equations (10), one receives the value of y_i as the following function:

$$y_i = U_{y_i}^{-1}(\phi_i \lambda_i) = Y_i(\lambda_i) \quad \forall i = 1, 2 \quad (22)$$

Note that equation (10) requires that the shadow prices λ_i have to be positive in an optimal solution for all i . Inserting $y_i = Y_i(\lambda_i)$ into the growth functions given by (8) and rearranging the terms of the conditions in (11), the equations of motion for the two state variables x_1 and x_2 and the two co-state variables λ_1 and λ_2 can be derived:

$$\dot{x}_i = G_i(\mathbf{x}) - \phi_i Y_i(\lambda_i) = \psi_i x_i \left(1 - \frac{\sum_{j=1}^n x_j}{\kappa}\right) - \phi_i U_{y_i}^{-1}(\phi_i \lambda_i) \quad \forall i \quad (23)$$

$$\dot{\lambda}_i = \lambda_i (\rho - G_{ix_i}) - V_{x_i} - \sum_{j \neq i} \lambda_j G_{jx_i} \quad \forall i \quad (24)$$

Conditions (23) and (24) describe the optimal dynamics of the system in state-costate space. To complete the necessary conditions for optimal solutions, the following transversality conditions are needed in addition to the initial conditions given

in (7).

$$\lim_{t \rightarrow \infty} \lambda_{it} x_{it} e^{-\rho t} \geq 0 \quad \forall i \quad (25)$$

Setting $\dot{\lambda}_1 = \dot{\lambda}_2 = \dot{x}_1 = \dot{x}_2 = 0$, the general steady state conditions of the system read as follows:

$$\bar{x}_i = \frac{\phi_i Y_i(\bar{\lambda}_i)}{\psi_i \left(1 - \frac{\sum_{j=1}^n \bar{x}_j}{\kappa}\right)} \quad \forall i \quad (26)$$

$$\bar{\lambda}_i = \frac{V_{\bar{x}_i} + \sum_{j \neq i} \bar{\lambda}_j G_{j\bar{x}_i}}{\rho - G_{i\bar{x}_i}} \quad \forall i \quad (27)$$

To be able to solve these conditions analytically, it is assumed that the instantaneous utility function $U(\mathbf{y})$ takes on the form of the isoelastic function $U(\mathbf{y}) = \ln(y_1) + \ln(y_2)$. It follows that $Y_i(\lambda_i) = U_{y_i}^{-1}(\phi_i \lambda_i) = \frac{1}{\phi_i \lambda_i}$ for $i = 1, 2$. The steady state conditions then are given by:

$$\bar{x}_1 = \frac{\phi_1 Y_1(\bar{\lambda}_1)}{\psi_1 \left(1 - \frac{\bar{x}_1 + \bar{x}_2}{\kappa}\right)} = \frac{\bar{\lambda}_1}{\psi_1 \left(1 - \frac{\bar{x}_1 + \bar{x}_2}{\kappa}\right)} \Leftrightarrow \bar{\lambda}_1 = \frac{1}{G_1(\mathbf{x})} \quad (28)$$

$$\bar{x}_2 = \frac{\phi_2 Y_2(\bar{\lambda}_2)}{\psi_2 \left(1 - \frac{\bar{x}_1 + \bar{x}_2}{\kappa}\right)} = \frac{\bar{\lambda}_2}{\psi_2 \left(1 - \frac{\bar{x}_1 + \bar{x}_2}{\kappa}\right)} \Leftrightarrow \bar{\lambda}_2 = \frac{1}{G_2(\mathbf{x})} \quad (29)$$

$$\bar{\lambda}_1 = \frac{V_{\bar{x}_1} + \bar{\lambda}_2 G_{2\bar{x}_2}}{\rho - G_{1\bar{x}_1}} \quad (30)$$

$$\bar{\lambda}_2 = \frac{V_{\bar{x}_2} + \bar{\lambda}_1 G_{1\bar{x}_1}}{\rho - G_{2\bar{x}_2}} \quad (31)$$

Considering the system (28 – 31), one can plug $\bar{\lambda}_2$ from equation (29) into equations (30) and (31) and solve the remaining three equations for λ_1 , each then depending only on x_1 and x_2 . These functions can then be plotted as surfaces in a 3D diagram. The intersection of all three surfaces constitutes the equilibrium of the system. The three resulting steady state conditions read as follows:

$$F_1 = \lambda_1 = \frac{1}{G_1(\mathbf{x})} \quad (32)$$

$$F_2 = \lambda_1 = \frac{V_{x_1} + \frac{G_{2x_1}}{G_2(\mathbf{x})}}{\rho - G_{1x_1}} \quad (33)$$

$$F_3 = \lambda_1 = \frac{\frac{\rho - G_{2x_2}}{G_2(\mathbf{x})} - V_{x_2}}{G_{1x_2}} \quad (34)$$

These equations represent isoclines in three dimensions. Note that an increase in λ_2 would shift the two isoclines (33) and (34) down, when depicting the isoclines in a 3D diagram with x_1 and x_2 at the base and λ_1 on the vertical axis. Equation (32) gives the combinations of x_1 and x_2 for which $\dot{x}_1 = 0$. Equation (33) gives the combinations for which $\dot{x}_2 = 0$ and $\dot{\lambda}_1 = 0$. Equation (34) gives the combinations for which $\dot{x}_2 = 0$ and $\dot{\lambda}_2 = 0$. The equilibria of the system occur where all three surfaces intersect. As all three functions are non-linear, a graphical illustration of all three surfaces in a 3D diagram can be quite confusing. However, it is possible to depict the intersections of all three surfaces with one another in a contour plot in x_1 - x_2 space. Equilibria occur where all three contours intersect. Figure 1 provides such a contour plot for the parameter values presented in Table 1 as an example.

4.4 Numerical example

In this subsection, a numerical example for a two-species renewable resource model with a biodiversity index is presented. Parameter values used are presented in Table 1. Species 2 features a higher intrinsic growth rate than species 1 but the same carrying capacity. Moreover, species 2 is damaged less by the same level of economic activity than species 1.

Parameter values			
ρ	0.01	κ	100
ψ_1	0.04	ψ_2	0.10
ϕ_1	0.2	ϕ_2	0.1

Table 1: Parameter values for the model with $\omega = 2$ and $n = 2$.

Figure 1 depicts the intersections of the three isoclines in x_1 - x_2 space. The red lines depict the intersections of the surfaces described by equations (33) and (34). The green and the blue lines depict the intersections of the surface described by equation (32) with the ones described by (33) and (34) respectively. The illustration shows that for these parameter constellations, there exists only one real-valued

equilibrium. The corresponding steady state values are given in Table 2. The eigenvalues of the Jacobian of the dynamic system evaluated at the steady state values have been computed. Two eigenvalues are positive while the other two are negative, which reveals that the determinant of the Jacobian is negative and shows that the steady state is a saddle.

Figure 1: Contour plot: Intersections of the three isoclines in x_1 - x_2 space.

Steady state values	
\bar{x}_1	19.6457
\bar{x}_2	21.6043
$\bar{\lambda}_1$	2.1660
$\bar{\lambda}_2$	0.7879
\bar{y}_1	2.3084
\bar{y}_2	12.6925
\bar{V}_2	1.9955

Table 2: Steady State values for the model with $\omega = 2$ and $n = 2$.

Note that the steady state stock \bar{x}_2 is larger than \bar{x}_1 , but that the two stocks are very evenly distributed. This results in a high steady state value of the biodiversity

index, \bar{V}_2 . Note also that \bar{y}_2 is much higher than \bar{y}_1 , which is due to the fact that the damage coefficient ϕ_2 and the steady state shadow price $\bar{\lambda}_2$ are smaller than ϕ_1 and $\bar{\lambda}_1$ respectively. The shadow prices depend among other things on the marginal value of the biodiversity index $V_{\bar{x}_i}$. As $\bar{x}_1 < \bar{x}_2$, it directly follows that $V_{\bar{x}_1} > 0$ while $V_{\bar{x}_2} < 0$, which influences the shadow prices in the way that $\bar{\lambda}_1 > \bar{\lambda}_2$.

As the biodiversity index is not concave for all combinations of x_1 and x_2 , it is necessary to explicitly check the sufficient conditions for the steady state to be a maximum. In order to do so, the Hessian matrix of the current-value Hamiltonian evaluated at the steady state values is analyzed in the following:

$$Hesse(H^c) |_{stst} = \begin{pmatrix} -0.1877 & 0 & 0 & 0 \\ 0 & -0.0062 & 0 & 0 \\ 0 & 0 & -0.0045 & 0.0006 \\ 0 & 0 & 0.0006 & -0.0035 \end{pmatrix} \quad (35)$$

The four eigenvalues of this Hessian are: $(-0.1877, -0.0062, -0.0048, -0.0032)$. The determinants of the leading principal minors are: $Det_1 = -0.1877$, $Det_2 = 0.0012$, $Det_3 = -5.25 \times 10^{-6}$, and $Det_4 = 1.77 \times 10^{-8}$. It can be observed that all four eigenvalues of the Hessian are negative and that the signs of the leading principal minors alternate, starting with a negative sign of Det_1 . Consequently, the current-value Hamiltonian is concave at the steady state. Moreover, both shadow prices are necessarily positive in steady state. Consequently, sufficient optimality conditions are fulfilled, which proves that there is a unique optimal steady state that solves the dynamic system. Also note that the off-diagonal elements of the Hessian are very close to zero, while all diagonal elements of the Hessian are negative. Sufficient optimality conditions will be fulfilled as long as this is the case and the off-diagonal elements of the Hessian are sufficiently close to zero.

4.5 Comparison to a model with a strictly increasing, concave value function

This subsection compares the results derived so far with those derived in a model where increases in the stocks of the living resources always add positively to the value derived from the existence of these resources. That is it compares the results

derived so far to the case where $V_{x_i} > 0$ holds for both living resources at all times and independently of the relative stock sizes and where $V(\mathbf{x})$ is strictly concave in x_1 and x_2 . To exemplify this, consider the following value function:

$$V_{new}(x_1, x_2) = \frac{\ln(x_1) + \ln(x_2)}{8} + \frac{3}{4} \quad (36)$$

The first partial derivatives of $V(\mathbf{x})$ with respect to both stock sizes now are positive for all possible combinations of stock sizes. Moreover, the function is strictly concave for all x_1 and x_2 . This functional form of the value function has been chosen to make it comparable to the biodiversity index. Its values are confined to the interval $[1, 2]$, which also holds for the biodiversity indices for $n = 2$.

The value function (36) has been substituted into the maximization problem (6-8) instead of the biodiversity index in order to compare results. Solutions for the real-valued equilibrium values are given in Table 3. The arrows indicate the change with respect to the results derived in the model with the biodiversity index. The value given in the last row of Table 3, \bar{V}_2 , is the value the Simpson-Index would take on in steady state. Note that this biodiversity index had not been considered in the welfare maximization problem here, so \bar{V}_2 represents the ex-post biodiversity, observed after the maximization with the new value function. Applying the new value function implies that both parts of the welfare function, i.e. $U(\mathbf{y})$ and $V_{new}(\mathbf{x})$, are now strictly concave on the whole domain so that the current-value Hamiltonian is also jointly concave in the control and state variables. Moreover, optimality conditions require that both shadow prices are positive in equilibrium. The properties of the Hessian matrix of the current-value Hamiltonian have also been checked. As expected, all eigenvalues of the Hessian are negative. Consequently, the steady state fulfills the usual sufficient optimality conditions.

Comparing the steady values of this example with that of subsection 4.4, one can see that the steady state stock of the more abundant species, \bar{x}_2 , increased while that of the less abundant species, \bar{x}_1 , decreased, i.e. the distribution of species abundances has become more uneven. In both model settings, restrictions on the shadow prices are such that both $\bar{\lambda}_1$ and $\bar{\lambda}_2$ have to be greater than zero in steady state. In the second model setting, the shadow price of the more abundant species, $\bar{\lambda}_2$, decreased and the corresponding control variable, \bar{y}_2 , increased. The increase in

Steady state values		
\bar{x}_1	18.6029	↓
\bar{x}_2	26.1029	↑
$\bar{\lambda}_1$	2.4304	↑
$\bar{\lambda}_2$	0.6928	↓
\bar{y}_1	2.0573	↓
\bar{y}_2	14.4334	↑
\bar{V}_2	1.52317	↓

Table 3: Steady State values for $n=2$ with a strictly increasing, concave value function

\bar{y}_2 directly follows from the decrease in $\bar{\lambda}_2$ as $\bar{y}_2 = \frac{1}{\phi_2 \bar{\lambda}_2}$ in steady state. The inverse holds in analogy for the shadow price and the control variable corresponding to the less abundant steady state stock, \bar{x}_1 .

Most importantly, the solution in the second model setting does no longer depend on *relative* stock sizes. This implies that the evenness of the distribution of relative species abundances does no longer matter for the optimization. Instead, now the absolute abundances of the living resources are important. The result is that the value of the Simpson-Index calculated after the steady state of the new system had been observed decreased considerably. While the Simpson-Index took on a value of nearly 2 in the first example, it now declines to approximately 1.5. On the other hand, it can be observed that the total number of individuals in steady state, i.e. $\bar{x}_1 + \bar{x}_2$, increased from 41.2 to 44.7. This result confirms expectations in that the choice of the value function influences the degree of evenness in the distribution of relative species abundances in steady state. Choosing a strictly increasing, concave value function induces steady states with lower evenness and thus with lower biodiversity in a setting with a given number of species n .

5 Discussion and conclusion

The model presented in section 4 of this paper introduces a biodiversity index that accounts for both species richness and evenness into an optimal control model. The model includes two living resources which grow according to a logistic growth func-

tion but which compete with one another for the same external resource that sustains their growth. Moreover, both living resources are damaged by an economic activity according to some damage parameter. The economic activity yields a net benefit represented by a utility function that is strictly increasing and jointly concave in the controls. Biodiversity is introduced into the model by using a value function that reflects the value derived from the existence of the two living resources. In a first setting, this value is represented by the Simpson-Index, a biodiversity index widely accepted by ecologists. In a second setting, this value is represented by a monotonically increasing, concave value function. To my knowledge, this is the first paper that studies the effects of introducing a biodiversity index into an optimal control model and comparing its application to that of a monotonically increasing, concave value function.

When using the biodiversity index, the signs of the marginal values of the resource stocks necessarily are of opposite signs as long as $x_1 \neq x_2$. The marginal value of the less abundant species then is positive while that of the more abundant species is negative. Moreover, the biodiversity index is locally concave only for $x_1 = x_2$ but not on the whole domain. This could induce non-concavity of the current-value Hamiltonian. However, this paper shows that it is possible to derive a unique equilibrium that satisfies sufficient conditions for a welfare maximum in spite of using a non-concave value function to express the value of the living resources. In addition, the analysis presented indicates that the properties of the biodiversity index crucially influence the equilibrium of the model. Once biodiversity is considered in the optimization problem, the stock sizes are distributed more evenly in steady state. This in turn implies, that using a monotonically increasing, concave value function to express the value of the living resources induces an equilibrium with lower species evenness and thus with lower biodiversity.

Several limitations apply to the simple model presented in this paper. First, the economic activity that yields utility via the utility function $U(\mathbf{y})$ is not modeled in more detail. A natural extension of the model would be to consider benefits and costs of this activity separately in more detail. One would then also be able to contrast the decision of a private economic agent, say a company, that does not care for biodiversity with the decision of a social planner that takes biodiversity into account. Consequently, such a set up would allow to determine efficient policy measures, e.g.

an optimal tax on the economic activity, in order to internalize external damages.

Second, one could argue that the flexible control approach presented in this paper is not fully realistic because damages caused by economic activities and inflicted upon living resources can not be controlled perfectly separately. However, a more rigid control approach with only one control variable would complicate the analysis and cause problems that would divert attention from the effects of introducing the biodiversity index in the model. In a setting with two species, using a more rigid control approach would allow for one shadow price to be negative as long as the other one is positive and sufficiently large. This leads to the appearance of several steady states, no matter if one uses the biodiversity index or the concave, monotonically increasing value function in the maximization framework. Moreover, sufficient conditions for maxima then are harder to check. Consequently, the more flexible control approach has been chosen here to show in a simple but clear setting that the biodiversity index can be used as a value function to express the non-use values derived from the existence of living resources in order to determine a unique and optimal steady state of the system.

Third, the model in this paper does not include spatial aspects. Living resources are not static but continuously change their location. In particular, they can wander between sites affected by the economic activity and e.g. protection sites. Consequently, possible extensions include the consideration of site selection and site preservation.

In spite of these limitations, the paper presents important insights of how considering biodiversity indices influences the optimal solution of multiple-species optimal control models. It can be seen as a starting point for further research building richer models and addressing the mentioned limitations.
